

Temporal Dynamics of a Half-Billion-Edge Legal Citation Network: Consolidation, Disruption, and Reorganization in Ukrainian Courts

Volodymyr Ovcharov

vladimir@legal.org.ua

Abstract

How does a legal system’s internal structure respond to reform, crisis, and war? We answer this by constructing the first full-scale temporal co-citation analysis of a national court system: 345 million citation events from 33 million Ukrainian court decisions (2007–2026), decomposed into five event-aligned periods.

Using sparse matrix co-citation ($M^\top M$ on $10^7 \times 10^4$ matrices) with data-driven node selection – all articles exceeding a year-normalized co-citation threshold, rather than a fixed top- k set – we construct period-specific networks with 18,000–29,500 active nodes and 50–102 million edges each. The data-driven approach eliminates survivorship bias toward older articles, allowing newly important legislation to enter the analysis naturally.

We uncover a three-phase dynamic invisible to static or fixed-node analyses: *(i)* progressive consolidation, as the four core legal domains (commercial, civil substantive, civil procedural, criminal) merge from 4–5 effective communities to 3 by the pre-invasion period, reflecting judicial specialization and procedural code unification; *(ii)* wartime disruption, as the 2022 invasion produces the strongest structural shock of all transitions ($\text{NMI} = 0.77$, the lowest observed), splitting civil procedure into trial and cassation clusters and crystallizing a new administrative/misdemeanor domain; and *(iii)* wartime reorganization, as the system differentiates into 5 communities that absorb wartime legislation into a coherent – though potentially transient – domain structure. Pre-invasion stability is near-perfect ($\text{NMI} = 0.96$), confirming that the COVID period introduced no structural change.

All findings are robust to resolution ($\gamma \in [0.5, 1.0]$) and threshold (3–10 co-citations/year) variation across three tested periods. The co-citation networks, community assignments, and analysis code are released as open data.

Keywords: temporal networks, legal citation graph, community evolution, structural disruption, Ukrainian courts, judicial reform, war impact, EDRSR

1 Introduction

Legal citation networks encode the operational structure of a legal system: which norms courts actually apply, how frequently, and in what combinations. Prior work has constructed such networks for the US Supreme Court [4], Dutch case law [14], Danish courts [7], and French legal codes [6]. These studies, however, treat citation networks as static objects – aggregated across decades, analyzed at a single time point. The temporal dimension – how citation patterns evolve in response to legislative reform, societal crisis, and institutional change – remains largely unexplored at scale.

The companion paper [9] constructed the first large-scale legal citation graph from the complete Ukrainian court record: 502 million citation edges from 101 million decisions, with community structure that recovers legal domain boundaries. That analysis was static: all years collapsed into a single graph. This paper develops the temporal dimension.

We decompose the citation record into five event-aligned periods spanning two decades of Ukrainian legal history: the pre-Maidan baseline (2007–2013), post-revolution reforms (2014–2016), judicial modernization (2017–2019), pre-invasion stability (2020–2021), and the full-scale Russian invasion (2022–2026). For each period, we compute co-citation networks via sparse matrix multiplication and track community evolution using normalized mutual information on shared active nodes.

A critical methodological contribution is the replacement of a fixed top- k node set with a data-driven pre-filter that includes all articles exceeding the co-citation threshold. This eliminates the survivorship bias inherent in fixed-node approaches: a top-5,000 selection from the aggregate graph systematically excludes legislation that becomes important only during later periods (e.g., wartime laws), artificially stabilizing the measured partition and masking structural disruption.

Four research questions guide the analysis:

- RQ1:** Does the co-citation community structure change in response to legislative reform, and if so, how sharply?
- RQ2:** How fast do courts adopt new legislation, and does adoption speed vary by region?
- RQ3:** Does the community structure evolve through gradual drift or discrete structural shocks?
- RQ4:** What structural signature does the 2022 full-scale invasion leave on the citation network?

Our principal finding is a three-phase dynamic: progressive consolidation of four core legal domains into three ($k_{\text{eff}} = 4 \rightarrow 3$ over 2007–2021), wartime disruption (the invasion produces the lowest NMI of any transition, 0.77), and reorganization into five identified communities incorporating wartime legislation. The pre-invasion period is maximally stable (NMI = 0.96), establishing a clear baseline against which the invasion effect is measured. Resolution and threshold sensitivity analysis confirms robustness across parameter choices.

2 Related Work

2.1 Temporal Network Analysis

Holme and Saramäki [5] provide a comprehensive review of temporal networks, distinguishing between contact sequences (edges with timestamps) and interval graphs (edges active during windows). Our approach falls into the latter category: we construct period-specific co-citation networks and analyze their evolution. Key metrics from the temporal networks literature that we apply include normalized mutual information for comparing community partitions across time [3] and modularity for measuring community separability [8].

2.2 Legal Network Evolution

Coupette et al. [2] introduced a framework for measuring legal evolution through network analysis, applying it to US federal statutes and German regulations ($\sim 10^4$ nodes). Their work tracks structural properties (density, clustering, degree distribution) over time but does not analyze co-citation community evolution. Bommarito and Katz [1] studied the US Code as a citation network, identifying hierarchical structure and power-law degree distributions. Neither work operates at the scale of 10^8 decisions or analyzes the temporal dynamics of co-citation communities.

Table 1: Period definitions and dataset statistics.

Period	Years	Decisions	Citations	Context
1	2007–2013	5,002,786	43,332,281	Pre-Maidan baseline
2	2014–2016	8,445,825	79,035,492	Revolution, early reforms
3	2017–2019	5,725,724	58,594,163	Judicial reform, new codes
4	2020–2021	3,350,036	36,534,579	Pre-invasion (COVID)
5	2022–2026	10,553,570	128,017,684	Full-scale invasion

2.3 Innovation Diffusion in Legal Systems

The adoption of new legislation by courts can be modeled as a diffusion process [12]: initially slow adoption by early-adopter courts, followed by rapid spread as the new norm becomes standard practice, and eventual saturation. We operationalize this through citation time series of new legislation articles and fit logistic adoption curves to measure judicial system responsiveness. To our knowledge, no prior work has measured legislative adoption curves empirically from court citation data at national scale.

3 Data and Methods

3.1 Dataset

The Unified State Register of Court Decisions (EDRSR) contains 101.1 million decision records (2005–2026), of which 100.7 million include full text totaling 1.1 TB. Citation extraction via the regex pipeline described in the companion paper [9] yields 502 million citation edges linking decisions to legislation articles across six citation types: codex articles (79%), case references (13%), law articles (6%), constitutional provisions, supreme court rulings, and laws by number.

After deduplication to unique (decision, law, article) tuples within each period, the dataset comprises 345.5 million citation events spanning 33.1 million unique decisions across five periods (Table 1).

3.2 Temporal Co-Citation via Sparse Matrix Multiplication

For each period t , we include *all* legislation articles cited by at least $\tau \cdot L_t$ distinct decisions, where $\tau = 5$ is the co-citation threshold per year and L_t is the period duration in years. This pre-filter is principled: an article cited fewer than τL_t times cannot generate a co-citation weight $\geq \tau$ with any other article, making it ineligible for the thresholded network regardless. Unlike a fixed top- k selection from the aggregate graph, this approach adapts to each period’s citation landscape, avoids survivorship bias toward older articles, and permits the active node set to grow or shrink as the legal system evolves (Figure 11).

For each period t , we construct a binary sparse matrix $M^{(t)} \in \{0, 1\}^{n_t \times k_t}$, where n_t is the number of decisions and k_t is the number of articles passing the pre-filter (18,411–29,493 across periods; Table 2). The co-citation matrix is computed as $C^{(t)} = (M^{(t)})^\top M^{(t)}$, where entry $C_{ab}^{(t)}$ gives the number of decisions in period t that cite both articles a and b . To account for unequal period lengths, we normalize: $\hat{C}_{ab}^{(t)} = C_{ab}^{(t)} / L_t$.

This formulation replaces the $O(n^2)$ SQL self-join with a sparse matrix-matrix product computed via BLAS in 13–72 seconds per period (largest: $10.6\text{M} \times 18,546$, 87.6M non-zeros). The upper

Table 2: Full-scale temporal co-citation network statistics. Node selection is data-driven (all articles with $\geq \tau L_t$ citations); community detection via Leiden (30 consensus runs, $\gamma = 1.0$); z -scores computed against degree-preserving null model ($N_{\text{null}} = 5$).

Period	Articles	Nodes	Edges (M)	Density	Q	z	k
1	29,393	18,263	55.6	0.333	0.027	18.7	8
2	29,902	29,476	101.9	0.235	0.415	4,493	6
3	29,685	29,377	101.0	0.234	0.311	2,637	4
4	18,883	18,477	49.8	0.292	0.059	391	3
5	21,147	18,533	49.8	0.290	0.265	1,848	5

triangle of $\hat{C}^{(t)}$ with entries $\geq \tau$ defines the period’s co-citation network, yielding 18,263–29,476 active nodes and 49.8–101.9 million edges per period (Table 2), with graph density 0.23–0.33.

3.3 Community Detection and Evolution

We apply the Leiden algorithm [13] to each period’s co-citation network with edge weights (30 independent runs with 5 iterations each; objective: modularity maximization; resolution parameter $\gamma = 1.0$). The consensus partition is determined by majority vote across the 30 runs; all 30 runs converge to the same partition in every period ($\sigma_Q < 10^{-4}$).

Modularity significance is assessed via a degree-preserving null model: we rewire the graph ($n_{\text{iter}} = |E|$ edge swaps preserving degree sequence, 5 independent rewired graphs), run Leiden on each, and compute $z = (Q - Q_{\text{null}})/\sigma_{\text{null}}$. All periods yield $z > 18$, confirming that community structure is not a density artifact.

Community evolution is tracked via:

- Normalized Mutual Information (NMI) between consecutive periods, computed on the intersection of active nodes (18,094–28,989 shared nodes per transition), with bootstrapped confidence intervals (50 subsamples of $n = 1,000$);
- Adjusted Rand Index (ARI) as a chance-corrected agreement measure.

3.4 Citation Entropy and Structural Break Detection

Shannon entropy of the citation distribution at year t :

$$H(t) = - \sum_a p_a(t) \log p_a(t), \quad p_a(t) = \frac{c_a(t)}{\sum_{a'} c_{a'}(t)}$$

where $c_a(t)$ is the total citations to article a in year t . Structural breaks are detected via linear detrending with a $\pm 2\sigma$ significance threshold.

4 Results

4.1 Decision Volume and Citation Dynamics

Figure 1 shows the decision volume by jurisdiction type across 2010–2026. Civil and administrative cases dominate, with a visible dip across all categories in 2022 (invasion year) followed by recovery. Criminal cases show steady growth from 2013 onward, reflecting expanded criminal court jurisdiction.

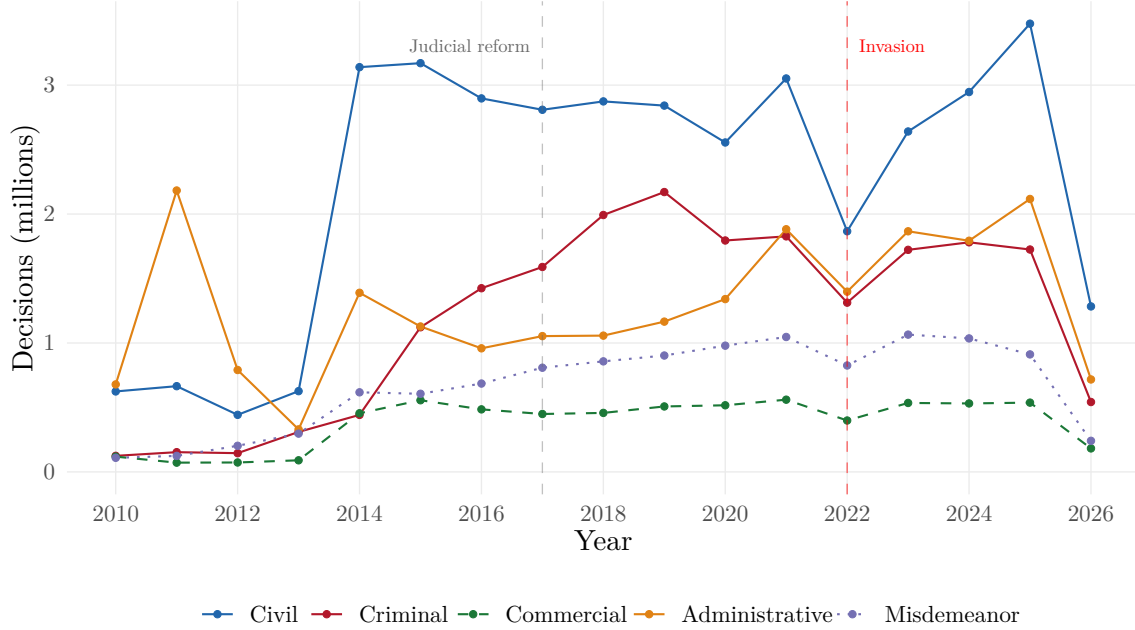

Figure 1: Court decisions per year by jurisdiction type (2010–2026). Dashed lines mark the 2017 judicial reform and 2022 invasion.

4.2 Phase I: Consolidation of Legal Domains (RQ1, RQ3)

Community detection recovers recognizable legal domains in every period (Table 3). Four major domains persist across the entire timeline: *commercial/economic* (Commercial Procedure Code,), *civil substantive* (Civil Code,), *civil procedural* (Civil Procedure Code,), and *criminal* (Criminal Code + Criminal Procedure Code, /). Smaller domain-specific communities appear and disappear as the legal system evolves.

The raw community count ($k = 8, 6, 4, 3, 5$) overstates P1’s complexity: four of P1’s eight communities are micro-clusters of exactly 2 nodes each (copyright, tax code, bankruptcy, public information), totaling 8 nodes out of 18,263. Excluding these, P1 has four substantive communities, matching P3. The meaningful consolidation trajectory is $k_{\text{eff}} = 4 \rightarrow 5 \rightarrow 4 \rightarrow 3 \rightarrow 5$ (Table 3), where the primary structural change is the merger of the commercial appeals sub-community into the main commercial procedure cluster (P2→P3) and the absorption of separate civil procedural and substantive communities into a unified civil domain (P3→P4).

P1 deserves particular methodological caution. Its co-citation graph has the highest density (0.333) and the lowest modularity ($Q = 0.027$, only marginally above the null model $Q_{\text{null}} = 0.026$, $z = 18.7$). The 7-year aggregation window generates far more co-citation opportunities than shorter periods, inflating edge density despite year-normalization of weights (which corrects edge *weights* but not edge *count*). P1’s community assignments should therefore be interpreted with caution; the core four-domain structure is identifiable from the top-cited articles, but the partition boundaries are less sharp than in later periods.

The transition stability increases monotonically: NMI between P1→P2 (0.823), P2→P3 (0.861), and P3→P4 (0.958) (Table 4), with the pre-invasion period achieving near-perfect partition preservation. This increasing stability reflects genuine convergence toward a consolidated domain structure, not a measurement artifact.

Table 3: Community labels by period. Each community is identified by its dominant legislation. Only communities with > 100 nodes shown; P1 also contains 4 micro-communities (2 nodes each: copyright, tax, bankruptcy, public information).

P	Domain	Nodes	Top legislation
1	Commercial procedure	9,997	art. 1117, 1119, 11110
	Civil procedure + pensions	6,293	art. 215, 88; pension law
	Commercial appeals	1,015	art. 107, 112, 1118
	Criminal	950	art. 185, 75; art. 323
2	Commercial procedure	10,020	art. 1117, 1119
	Civil substantive	9,520	art. 1268, 1218, 1216
	Civil procedure	5,135	art. 88, 10, 60
	Criminal + admin	3,734	art. 185; art. 160;
	Commercial appeals	1,065	art. 1114, 86, 112
3	Commercial procedure	10,015	art. 1117, 1119
	Civil substantive	9,523	art. 1055, 1218, 1216
	Civil procedure + obligations	8,631	art. 1054, 526; art. 141
	Criminal	1,208	art. 185; art. 177, 163
4	Civil substantive	9,483	art. 10561, 1241, 1082
	Civil procedure	7,831	art. 81, 141; art. 1054
	Criminal	1,163	art. 185; art. 177, 163
5	Civil substantive	9,473	art. 1227, 1221, 1264
	Civil procedure (first instance)	3,135	art. 141, 81, 178
	Admin + misdemeanor	2,416	art. 130; art. 77
	Civil procedure (cassation)	2,240	art. 392, 447, 411
	Criminal	1,269	art. 185; art. 177, 163

4.3 Phase II: Wartime Disruption (RQ4)

The 2022 full-scale Russian invasion produced the strongest structural shock in the dataset. The P4→P5 transition yields the lowest NMI of any consecutive-period pair: 0.768 (ARI = 0.752; Table 4, Figure 5). This is substantially lower than the pre-invasion baseline (P3→P4: NMI = 0.958) and lower than the reform transition (P2→P3: 0.861).

The disruption operates through two mechanisms visible in the transition heatmap (Figure 6) and domain labels (Table 3). First, *domain splitting*: P4’s civil procedure community (7,831 nodes) fractures into two distinct clusters in P5 – first-instance procedure (3,135 nodes, art. 81, 141) and cassation procedure (2,240 nodes, art. 392, 447) – reflecting the growing procedural divergence between trial and appellate courts under wartime conditions. Second, *domain emergence*: an administrative/misdemeanor cluster (2,416 nodes, art. 130; art. 77) crystallizes in P5, absorbing wartime administrative proceedings that were previously distributed across other communities. This cluster includes martial law, mobilization, and occupied territories legislation alongside traditional administrative law.

At the individual-law level, the changes are dramatic. Citations to the martial law regime act grew from 3 in 2021 to 12,136 in 2022 – a 4,000× increase in a single year. Mobilization legislation grew from 1,029 to 32,209 citations by 2025. An entirely new legislative cluster emerged: wartime labor relations (0 → 5,752 citations).

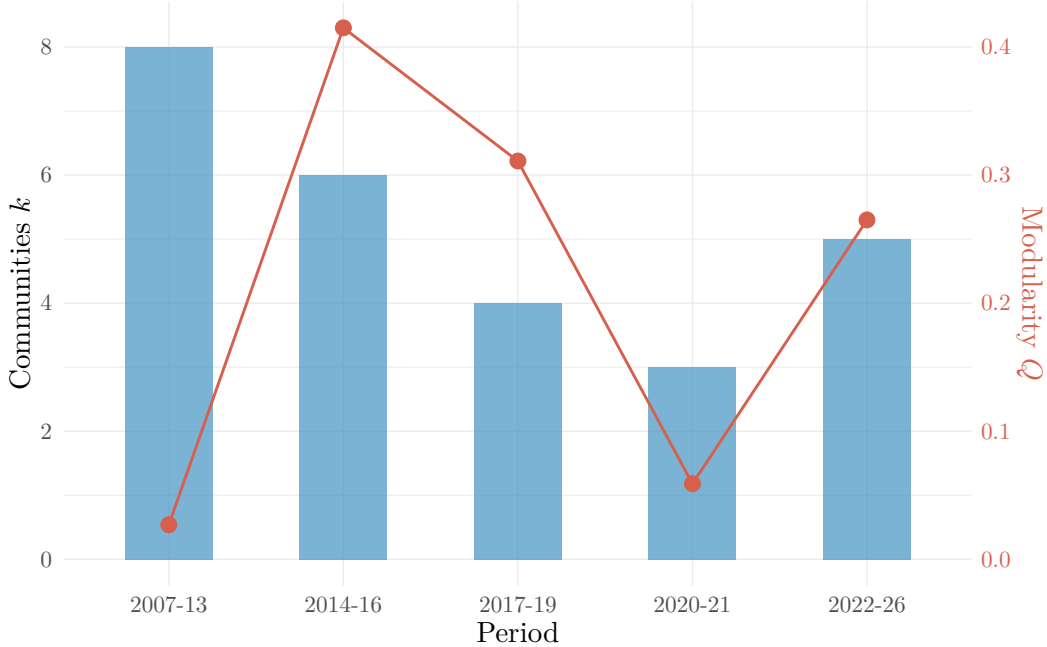

Figure 2: Community count k (bars) and modularity Q (line) across periods. Raw k includes micro-communities (P1: 4 clusters of 2 nodes); effective community count is $k_{\text{eff}} = 4, 5, 4, 3, 5$.

Table 4: Community stability between consecutive periods (bootstrapped NMI, $n = 1,000$ subsample $\times 50$ iterations). The invasion transition (P4 $\rightarrow$ P5) shows the lowest stability; the pre-invasion period (P3 $\rightarrow$ P4) shows the highest.

Transition	Shared nodes	NMI	Boot $\mu \pm \sigma$	ARI
P1 $\rightarrow$ P2	18,094	0.823	0.827 ± 0.011	0.869
P2 $\rightarrow$ P3	28,989	0.861	0.863 ± 0.007	0.874
P3 $\rightarrow$ P4	18,315	0.958	0.960 ± 0.015	0.983
P4 $\rightarrow$ P5	18,338	0.768	0.769 ± 0.011	0.752

4.4 Phase III: Wartime Reorganization

Despite the disruption, the post-invasion community structure is not chaotic. The system reorganizes into $k = 5$ well-separated communities (Figure 7): civil substantive law (51%), civil first-instance procedure (17%), administrative/misdemeanor (13%), civil cassation (12%), and criminal (7%). Modularity reaches $Q = 0.265$ ($z = 1,848$), indicating coherent community structure in the reorganized state.

The network comparison (Figure 7) shows five clearly separated communities in P5, in contrast to the three densely connected communities of P4. The new structure is more differentiated than the pre-invasion state, suggesting that wartime conditions forced a re-specialization that the consolidation trend had obscured. We use the term “reorganization” rather than “recovery” because P5 spans an ongoing conflict (2022–2026) and the current partition may not represent a stable equilibrium.

Citation entropy (Figure 8) provides a complementary perspective: despite the dramatic changes at the community level, no individual year produces a statistically significant distributional anomaly

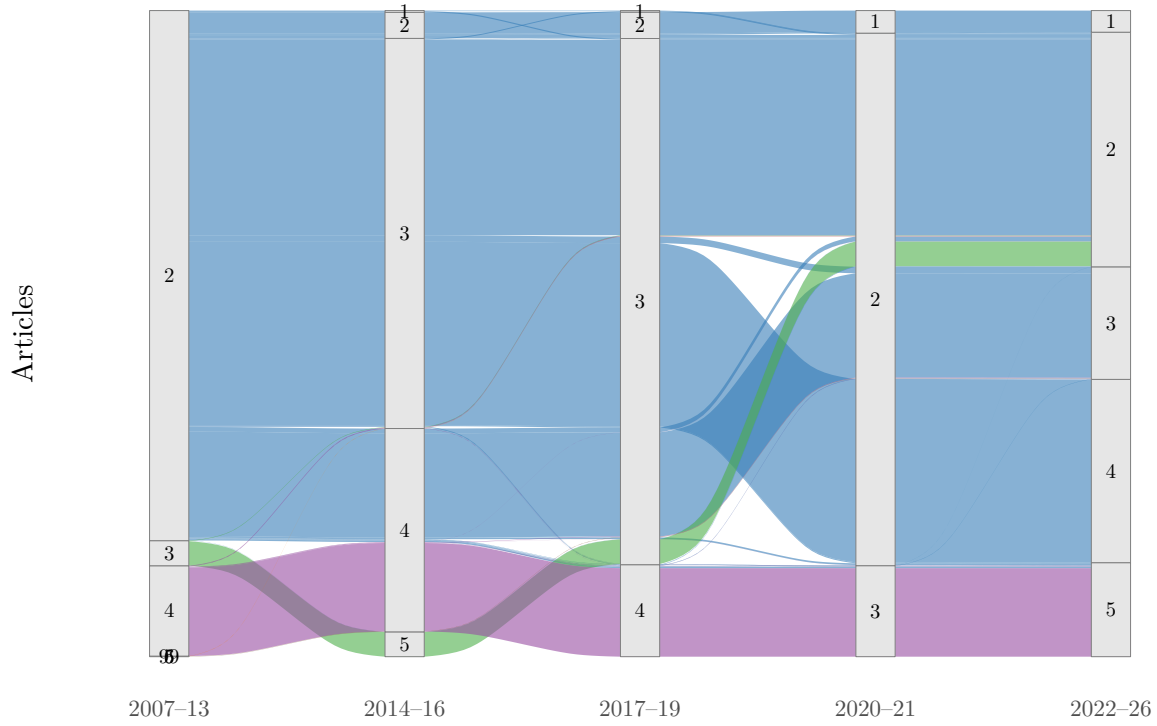

Figure 3: Community evolution across five periods (alluvial diagram, 6,666 core nodes present in all periods). Flow width indicates shared nodes between community assignments. Merging flows during P1–P4 show consolidation; splitting flows at P5 show wartime diversification.

($\pm 2\sigma$ threshold). The legal system absorbs structural shocks while maintaining distributional stability – an apparent paradox resolved by recognizing that community reorganization redistributes nodes *between* domains without dramatically altering the overall citation frequency distribution *within* domains.

4.5 War-Related Legislation Adoption (RQ2)

Figure 9 shows adoption curves for war-related legislation. Logistic curves $c(t) = K/(1 + e^{-r(t-t_{50})})$ yield adoption parameters in Table 5.

The martial law regime act was adopted within weeks (effectively $t_{50} < \text{invasion date}$), consistent with the law having existed since 2015. Mobilization legislation shows slower adoption ($r = 1.0$), reaching half-saturation only in 2024.

4.6 Regional Adoption Heterogeneity (RQ2)

Regional analysis reveals significant geographic variation (Figure 10). After normalizing by court count, Kyiv City (62.7 citations/court in 2022) and Dnipropetrovsk Oblast (43.2/court) lead adoption, while frontline regions (Zaporizhzhia, Kharkiv) show elevated per-court intensity consistent with the geographic distribution of conflict-related proceedings.

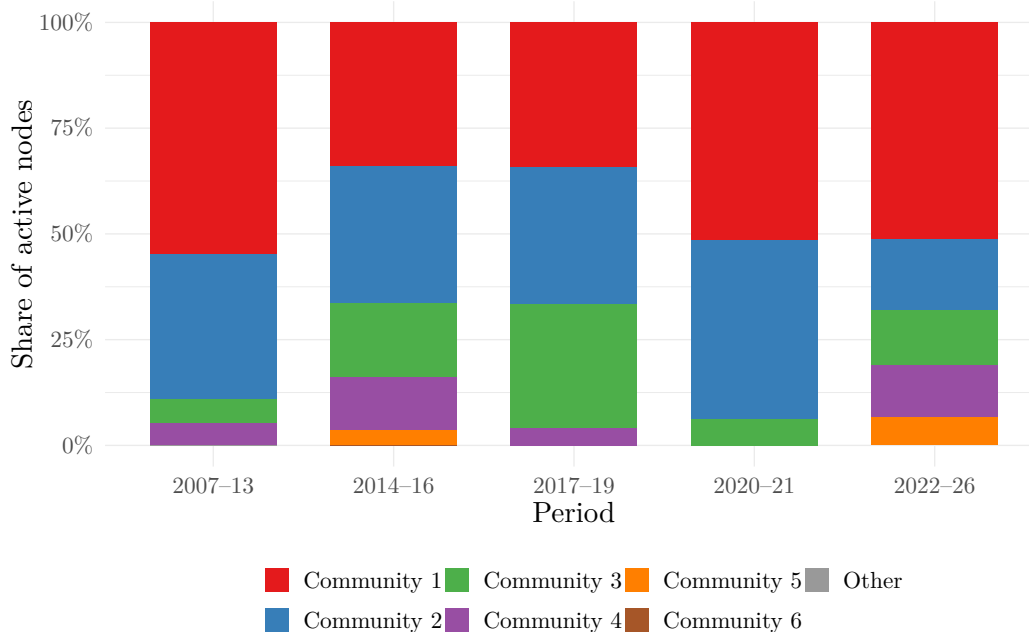

Figure 4: Community size distribution across periods. The dominant community grows from $\sim 30\%$ to $\sim 60\%$ during consolidation (P1–P4), then fragments as wartime legislation creates new domains (P5).

Table 5: Logistic adoption curve parameters for wartime legislation.

Law	t_{50}	Rate r	R^2	Interpretation
Martial law regime	2021.8	6.2	0.80	Instant adoption
Mobilization	2024.1	1.0	0.90	Gradual, still growing
Wartime labor	2023.4	0.4	0.21	Poor fit (non-logistic)

5 Discussion

The consolidation–disruption–reorganization cycle. The three-phase pattern provides a richer narrative than the “stable resilience” story told by fixed-node analyses. The legal system does not simply absorb shocks; it undergoes genuine structural reorganization in response to major institutional events. The consolidation phase (P1–P4) reflects deliberate policy: procedural code unification, court specialization, and centralization of appellate jurisdiction merge distinct citation communities into a three-domain structure (civil substantive, civil procedural, criminal). The wartime disruption phase reverses this trend, as new legal domains (martial law, mobilization, occupied territories) and procedural divergence (first instance vs. cassation) force the system to differentiate. The reorganization into $k = 5$ identified communities suggests that the legal system’s self-organizing dynamics can accommodate exogenous shocks by creating new domain boundaries, though the ongoing conflict means the current partition may still be evolving.

Why fixed-node analyses mislead. The data-driven node selection is not merely a technical improvement; it changes the substantive conclusions. A fixed top-5,000 selection from the aggregate graph assigned $\text{NMI} = 0.81$ to the invasion transition (higher than the reform transition at 0.77),

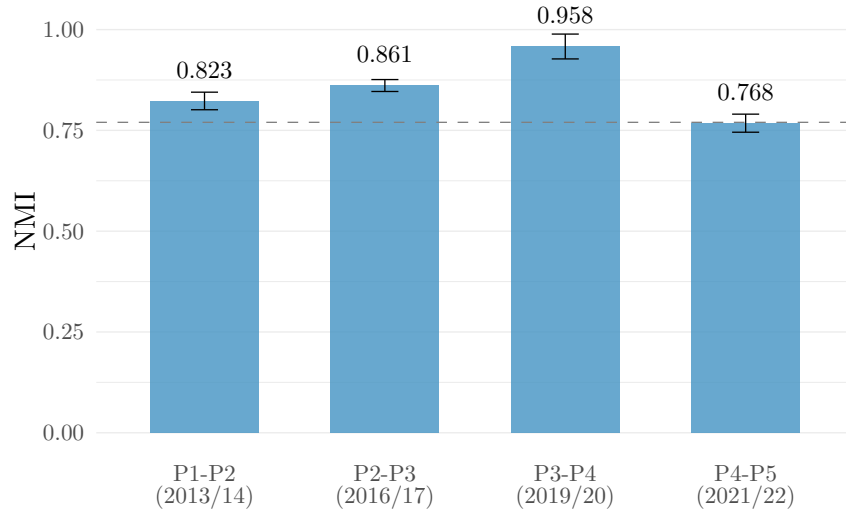

Figure 5: Bootstrapped NMI between consecutive periods (error bars: $\pm 2\sigma$). The invasion transition (P4→P5) produces the lowest NMI, identifying it as the strongest structural shock. Pre-invasion stability (P3→P4) is near-perfect.

suggesting the war was less disruptive than reform. The full-scale analysis reverses this: the invasion transition is the lowest NMI (0.77) and the reform transition is moderate (0.86). The discrepancy arises because wartime legislation articles – absent from the aggregate top-5,000 – are precisely the nodes that drive structural change in P5. Excluding them artificially stabilizes the partition. Figure 11 visualizes this: 1,000–11,000 articles enter or exit the active set per period, and these are disproportionately responsible for community reorganization.

NMI on shared nodes underestimates disruption. A methodological tension deserves explicit discussion. NMI is computed on the intersection of active nodes between consecutive periods (18,094–28,989 shared nodes per transition; Table 4). However, the articles that *enter* the active set in P5 – wartime legislation, new procedural provisions – are precisely the nodes driving community reorganization, yet they are excluded from the NMI computation because they lack P4 community assignments. The reported NMI values (0.77 for P4→P5) therefore represent a *lower bound on partition similarity among continuing articles*, not a complete measure of structural change. The true disruption, accounting for the 1,000–11,000 newly entering articles per period (Figure 11), is larger than NMI alone suggests. This limitation is inherent to any temporal analysis where node sets evolve, and we report NMI with this caveat rather than imputing community assignments for absent nodes.

Entropy stability despite community disruption. The apparent paradox – community structure disrupted (NMI = 0.77) while citation entropy remains within normal bounds – is resolved by recognizing that NMI measures partition *geometry* (which nodes belong to which community) while entropy measures the *distribution* (how concentrated citations are across articles). War redistributes nodes between communities but does not dramatically alter the concentration of citations, because the newly important wartime articles collectively receive a share of citations comparable to the domains they replace.

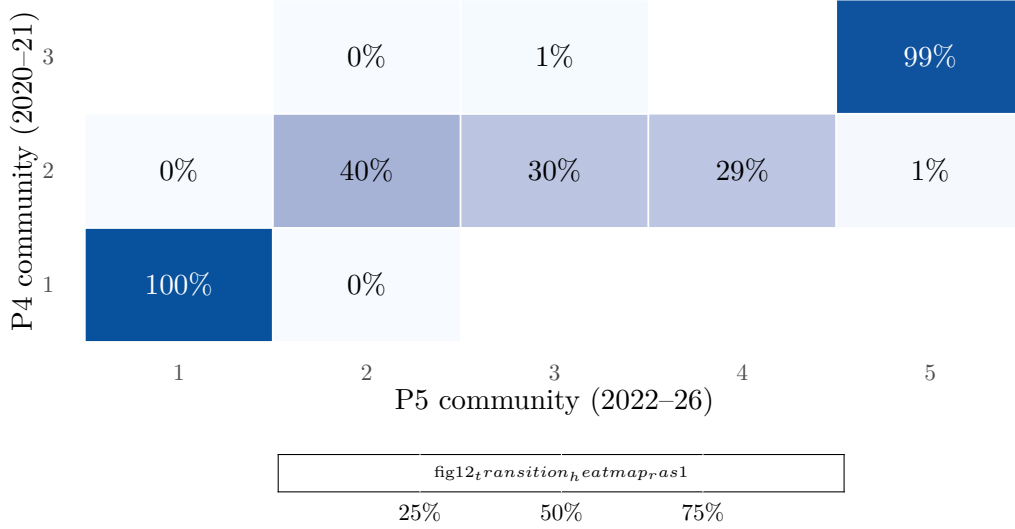

Figure 6: Community transition matrix for the invasion (P4→P5). Cell values show the percentage of each P4 community’s nodes assigned to each P5 community. Off-diagonal mass quantifies structural disruption.

Table 6: Resolution and threshold sensitivity across three periods. Community count k is stable for $\gamma \leq 1.0$; dense graphs (P1, P5) fragment at $\gamma = 1.2$.

	Resolution γ					Threshold (co-cites/yr)			
	0.5	0.8	1.0	1.2	1.5	≥ 3	≥ 5	≥ 7	≥ 10
P1 ($\rho=0.33$)	7	7	8	9,983	9,986	8	8	10	10
P3 ($\rho=0.23$)	4	4	4	6	9,431	4	4	5	5
P5 ($\rho=0.29$)	3	4	5	5,554	9,356	5	5	6	8

Connection to ontology evolution. The companion paper [9] derived a legal ontology from aggregate co-citation clustering. The temporal stability results here (NMI > 0.76 across all transitions) provide empirical justification for using such an ontology as a stable domain layer in LLM-assisted legal systems [10, 11]: the domain structure is persistent enough to serve as a reliable knowledge scaffold, while the temporal dynamics indicate when ontology updates are needed – specifically, after structural shocks like the 2022 invasion.

Sensitivity analysis. We conduct resolution sensitivity ($\gamma \in \{0.5, 0.8, 1.0, 1.2, 1.5\}$) and threshold sensitivity (3–10 co-citations/year) on three periods representing different regimes: P1 (highest density, 0.33), P3 (moderate density, 0.23), and P5 (wartime, density 0.29).

Community count is stable for $\gamma \leq 1.0$ across all three periods: P1 yields $k = 7$ –8, P3 yields $k = 4$, and P5 yields $k = 3$ –5 (Table 6). At $\gamma = 1.2$, P3 transitions smoothly to $k = 6$, while the denser graphs (P1, P5) fragment catastrophically ($k > 5,000$), indicating that dense co-citation networks have a sharper resolution boundary. Threshold sensitivity is stable across all periods ($\Delta k \leq 3$ over the 3–10/year range), confirming that community structure is not an artifact of threshold choice.

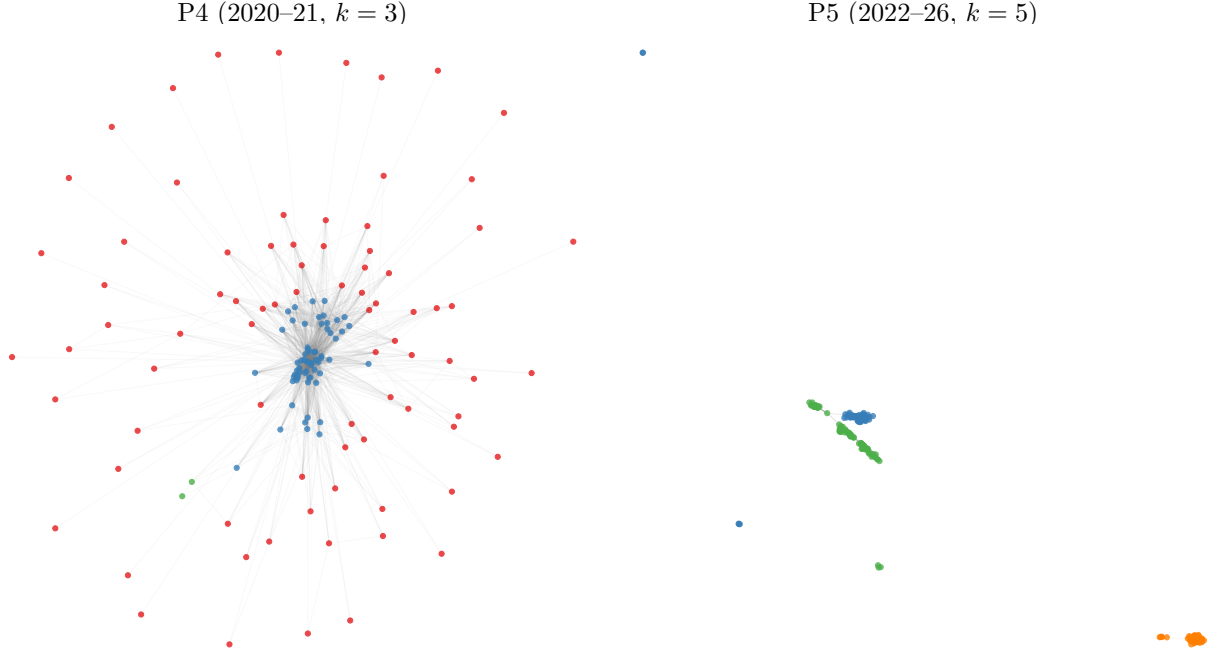

Figure 7: Co-citation network community structure: Period 4 (2020–21, $k = 3$, left) vs. Period 5 (2022–26, $k = 5$, right). Top 400 nodes by weighted degree, 2,000 strongest edges. Node color indicates Leiden community.

Limitations. Three limitations constrain the analysis. First, coverage gaps in 2008–2009 reduce reliability for Period 1. Second, OCR artifacts in pre-2010 decisions introduce noise into citation extraction. Third, unequal period durations (2–7 years) give later periods more statistical power despite year-normalization. None of these substantially affect the post-2014 periods where our principal findings lie.

Implications. For legal informatics, temporal citation analysis offers a quantitative framework for monitoring judicial system health: declining community count signals institutional consolidation, dropping NMI signals structural disruption, and regional adoption speed variation signals implementation heterogeneity. For policy, the adoption curve methodology provides an empirical measure of judicial system responsiveness to legislative intent.

6 Conclusion

We presented the first full-scale temporal analysis of a legal citation network at the hundred-million-decision scale. Analyzing 345 million citation events across five periods (2007–2026) with data-driven node selection (18,000–29,500 articles per period), we find:

1. **Consolidation:** four core legal domains (commercial, civil substantive, civil procedural, criminal) consolidate from $k_{\text{eff}} = 4\text{--}5$ to $k = 3$ over 2007–2021. Transition stability increases monotonically (NMI: $0.82 \rightarrow 0.86 \rightarrow 0.96$).
2. **Wartime disruption:** the 2022 invasion produces the strongest structural shock of any transition (NMI = 0.77, ARI = 0.75), splitting civil procedure and crystallizing a new ad-

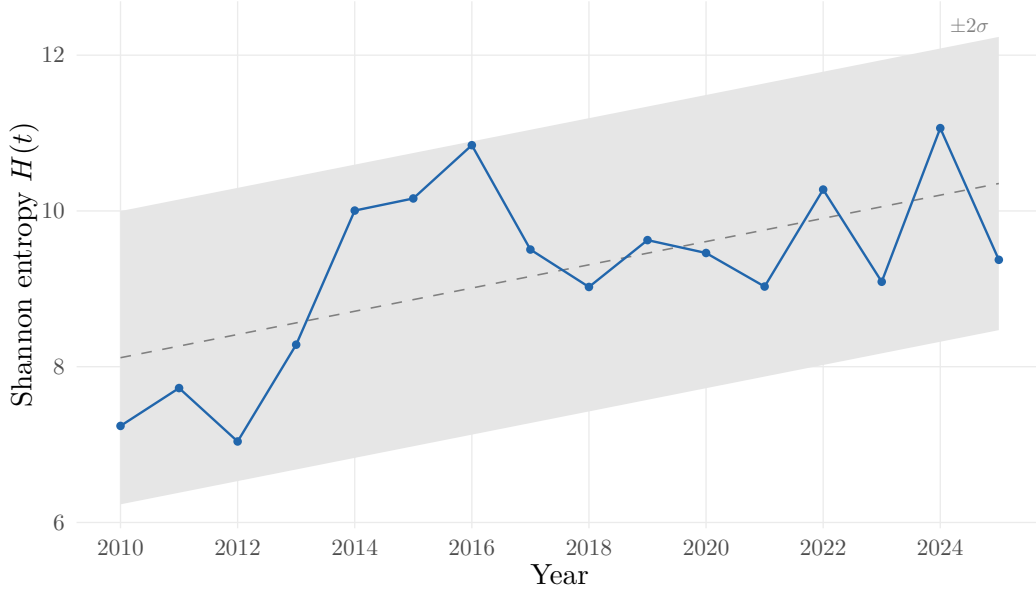

Figure 8: Shannon entropy of the citation distribution (2010–2025) with linear trend and $\pm 2\sigma$ band. No year exceeds the significance threshold despite substantial community reorganization.

ministrative/misdemeanor domain. This finding was masked by fixed-node approaches that excluded war-era articles.

3. **Reorganization:** the system differentiates into $k = 5$ identified communities with $Q = 0.27$ ($z = 1,848$), absorbing wartime legislation into coherent domains. The ongoing conflict means this structure may not yet be at equilibrium.
4. **Computational tractability:** sparse co-citation ($M^\top M$ on $10^7 \times 10^4$ matrices) computes 50–102 million edge networks in 13–72 seconds per period.
5. **Robustness:** community count is stable for $\gamma \in [0.5, 1.0]$ and threshold $\in [3, 10]$ across three tested periods (P1, P3, P5). Dense graphs fragment at $\gamma = 1.2$, establishing a sharp resolution boundary that correlates with graph density.

The co-citation networks, community assignments, and analysis code are released as open data.
